Received 24 September 2010; Accepted 18 April 2011

Abstract – The golden mussel *Limnoperna fortunei* was introduced into Argentina in 1991 and has since been spreading through the Plata and Guaíba basins at a rate of 240 km.year⁻¹. To assess their ability to invade the Andean tributaries of the Plata Basin (Pilcomayo, Bermejo and Salado del Norte rivers), their current range was assessed and related to the abiotic parameters of sites where they were present and absent. These data were then compared with their known tolerances to identify possible barriers to invasion. Outputs suggested that three environmental parameters are barriers to invasion: salinity and river flow intermittence in different sectors of the rivers Pilcomayo and Salado del Norte, and concentration of suspended sediments in the Bermejo River and in the upper reaches of the Salado del Norte and Pilcomayo rivers. The importance of these findings is discussed in relation to using environmental data to infer the invasion possibilities and the utility of environmental data to better understand invasion patterns and processes.

Key words: Abiotic parameters / barrier dispersion / bioinvasion / freshwater / golden mussel / *Limnoperna* sp.

Introduction

A consequence of globalization is the change of natural environments and species communities. With the exception of climate change, biological invasions probably have received more attention in recent years than any other ecological topic. In the past 10 years, a large number of papers, books, workshops and symposia addressing biological invasions were made (Davis, 1999). Geographic scale, frequency, and number of native and non-native species involved have increased dramatically over the past few decades (Emerton and Howard, 2008). Currently, introduced species are a main driver of biodiversity loss after habitat destruction (IUCN, 2000). Their negative impacts affect three essential components of biodiversity: landscape, species and genetic structure (Carlton, 1996). A further issue is the global biotic homogenization that arises from increased introductions as native and endemic species become displaced, leading to an increased similarity of biotic communities over time and space (Rahel, 2002).

The term “invasiveness” refers to the ability of an introduced species to invade a given habitat and

“invasibility” to the characteristics of a potential new habitat. In combination, these help determine the chances of establishment and dispersal of the introduced species (Marco *et al.*, 2002). Thus, the ability of an introduced species to become invasive is determined through a complex interaction of the characteristics of the species, the native communities and the receiving habitat (Marco *et al.*, 2002). To help prevent invasions, preventative and control measures may be used: predictive risk assessment, early detection, quick response and public education (Kluza and McNyset, 2005). Despite their ability to minimize the biotic homogenization of regions, there has been no formal implementation of these tools in South America (Darrigran *et al.*, 2004) and instead invasions are dealt with in a reactive manner, *i.e.*, when the species are already dispersing and impacting (Darrigran and Damborenea, 2006).

Information on native and introduced biodiversity in the Neotropical region is scarce and often only found in cryptic literature (Orenzans *et al.*, 2002). Under these circumstances, the description of species abundance distribution (SAD) within a community becomes important in understanding biodiversity patterns (McGill *et al.*, 2007). In 1991, golden mussel *Limnoperna fortunei*

*Corresponding author: invasion@fcnym.unlp.edu.ar

(Dunker 1857) was found while studying SAD in the Río de la Plata estuary (Pastorino *et al.*, 1993). This species soon started to rapidly disperse at a rate of 240 km·year⁻¹ (Darrigran, 2002) and became a serious macrofouling organism (Darrigran, 2010; Darrigran and Damborenea, 2011), and its impact may become as significant as that of the invasive zebra mussel *Dreissena polymorpha* (Pallas 1771) in North America (Claudi and Mackie, 1994). Indeed, the invasive potential of *L. fortunei* is revealed by its sharing of a number of biological characteristics with *D. polymorpha* (Morton, 1977), including its free-swimming planktonic larvae (Darrigran *et al.*, 2007), byssal filaments for attachment to hard substrates, high resistance to air exposure (Montalto and Ezcurra de Drago, 2003; Darrigran *et al.*, 2004) and high reproductive potential (Darrigran *et al.*, 2003). Since *L. fortunei* was introduced in South America, there have been attempts to understand the pattern of invasion and the rate of dispersion in order to better comprehend its bioinvasion processes (Darrigran, 2002; Darrigran and Damborenea, 2005; Boltovskoy *et al.*, 2006). Given the likelihood that *L. fortunei* will eventually invade North America and Europe, such studies may have global significance (Ricciardi, 1998; Darrigran and Pastorino, 2004; Darrigran *et al.*, 2007; Karatayev *et al.*, 2007a; Oliveira *et al.*, 2010a, 2011).

The rate of spread of introduced species depends on spatial scale and the extent to which both abiotic parameters and human activities accelerate or inhibit this process. A hierarchy of spatial scales exists, covering the range global, continental, regional, local (smaller units), water-body and habitat (Karatayev *et al.*, 2007b). While this spatial hierarchy is useful for predicting potential dispersion of invading bivalves, erroneous predictions are possible if the invasibility of a spatial higher scale is appraised that disregards the invasibility power of the immediately lower spatial hierarchy and the invasiveness of the species considered. On the basis that a prediction of the potential distribution of invasive species can be made at different spatial scales of resolution (Karatayev *et al.*, 2007b), the invasiveness of *L. fortunei* was considered in the Pilcomayo, Bermejo and Salado del Norte rivers, Argentina. The aim was to investigate the distribution of *L. fortunei* in these rivers and relate their presence and absence to a series of environmental and physicochemical parameters to ascertain whether any of these were acting as effective barriers to the invasion.

Material and methods

Study area

The sampling of *L. fortunei* in the Pilcomayo and Bermejo rivers, the upper basin of the Salado del Norte River, and in the Lower Paraguay River, covered its present range and also non-invaded areas. This area drains about 21% of the Plata Basin (3 140 000 km²) (UNL, 2005). The sampled rivers cross different ecoregions. Their

headwaters lie mainly in the arid/semiarid or in the wet Andes and flow downstream through dry and wet areas of the Chaco Plain. These strong changes suggest a vision of the river as a “discontinuum”, highlighting the non-uniform or patchy distribution of habitats and emphasizing habitat heterogeneity at the scale of meters–kilometers (Frissel *et al.*, 1986; Poff, 1997; Benda *et al.*, 2004). The characteristics of each river are as follows.

Pilcomayo River

This flows along 1600 km, draining a 281 000 km² basin with variable geomorphological, hydrological and hydrochemical characteristics. Considering the characteristics of this river, the key factors for this research are (1) river regime (Haines *et al.*, 1988; Roche *et al.*, 1989), (2) geomorphological channel characteristics (Martín Vide *et al.*, 2007), (3) amount and deposition rate of suspended sediments and discharge rate variations (Roche *et al.*, 1989; Amarilla and Amsler, 2005; Martín Vide *et al.*, 2007), (4) stream-flow variation (EVARSA, 2000; Goniadzki *et al.*, 2007; Martín Vide *et al.*, 2007), and (5) water salinity (Cordini, 1947).

Bermejo River

This system has a catchment area of 133 000 km² and a length of 1800 km (Fig. 1) (Soldano, 1947). It is perennial despite the moderate early summer regime (Haines *et al.*, 1988), with flow peaks in summer and minimum levels in late autumn, winter and early spring. The most important characteristics of this river are the large suspended sediment load (more than 150 × 10⁶ t·year⁻¹) (Drago and Amsler, 1988; Amsler and Drago, 1999) and a low salinity (less than 0.4 g·L⁻¹), from its headwaters to the mouth.

Salado del Norte River

Its basin covers 247 000 km², being the longest river in Argentina with 2000 km length (Fig. 1). Drought phases occur because the river course runs across the “arid diagonal” (Bonetto, 1994) and also because of its allochthonous character, high rates of infiltration, and diversion and damming of its flow for irrigation purposes. The upper segment carries high sediment loads (Drago and Paira, 1997). There are also changes in salinity; the headwater streams usually yield low salinities (< 0.5 g·L⁻¹), increasing to 1.3–96.0 g·L⁻¹ in the middle and lower segments of the Salado del Norte River (Drago and Quirós, 1996; Drago and Paira, 1997). Along its lower segment the river changes its intermittent flow regime and loses its allochthonous character due to the confluence of the Calchaquí River. The input of this river and of several other tributaries (ranges from 2 to 96 g·L⁻¹) increases its salinity, determining a mean salinity of 6 g·L⁻¹ for the Lower Salado del Norte River (Drago and Paira, 1997).

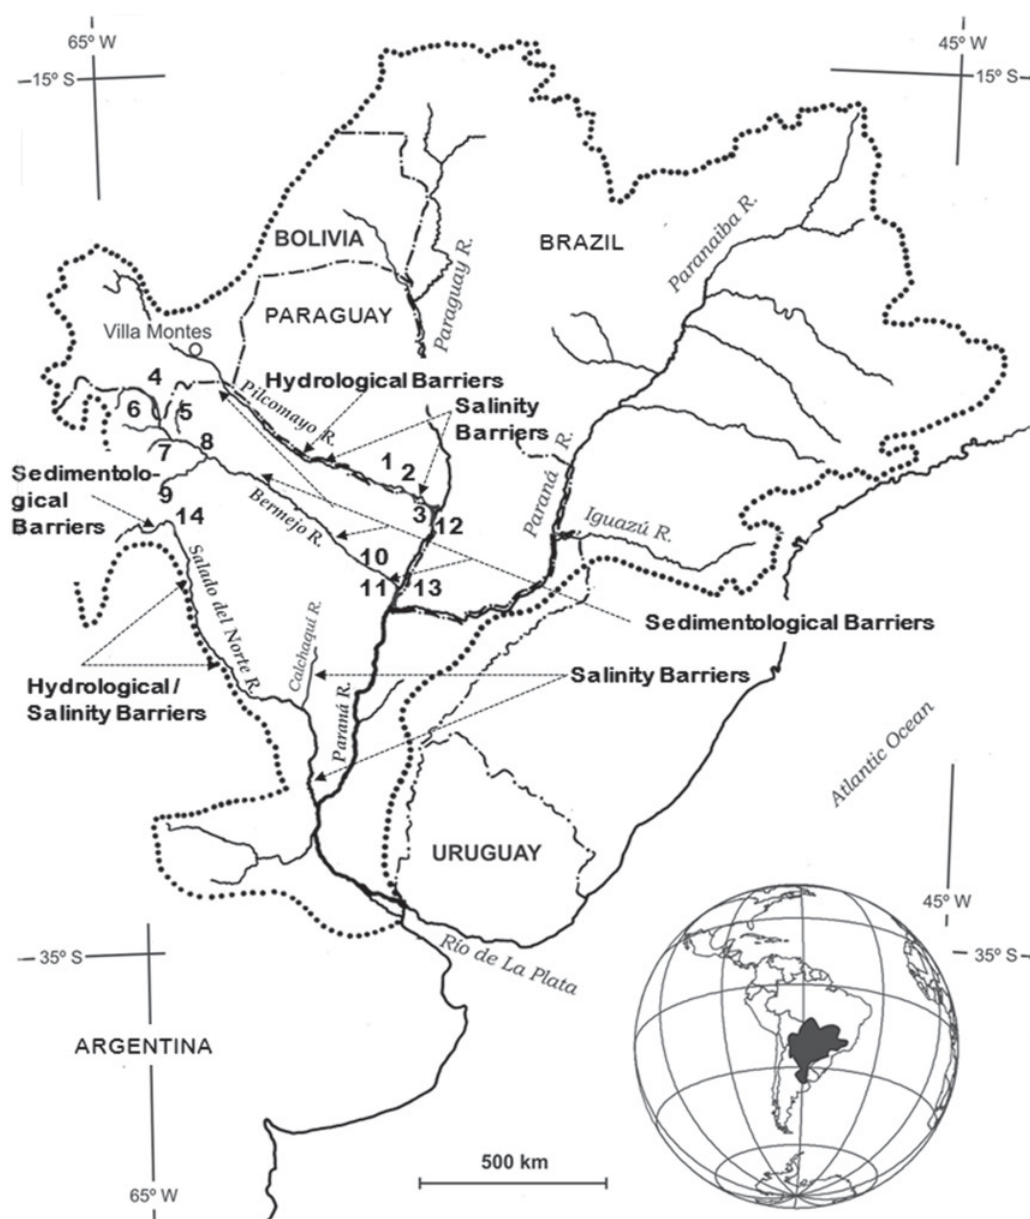

Fig. 1. The Plata Basin and the sampling stations in the Pilcomayo (1, 2, 3), Bermejo (4–11), Lower Paraguay (12, 13) and Salado del Norte (14) rivers. Locations of the hydrological, sedimentological and salinity barriers avoiding the invasion of the *L. fortunei* in the studied rivers are indicated.

Sampling regime

Across the rivers, 14 selected sites were sampled during a low-water period from 15 to 25 November 2005 (Fig. 1, Table 1). The presence/absence of adults of *L. fortunei* in sampling sites was determined qualitatively by visual inspection in the available substrates (the aquatic vegetation, submerged dredge-out blocks, rocky exposures, and built in-stream structures along the banks and riverbed), for a period of at least 60 min, conducted by two researchers. A quantitative sampling of larvae was also performed, filtering 100 L through to 35 μm mesh. The absence of larvae in the samples was interpreted as the

absence of a reproducing population since the survey was made in the golden mussel breeding season.

At each sampling site (SS), the following environmental factors were also determined: elevation (m a.s.l.), water velocity, water and air temperature, salinity (water checker Hach 44600), pH, transparency (Secchi disc), suspended sediments (size < 62 μm), suspended organic matter, dissolved organic matter, dissolved oxygen and calcium (as Ca^{2+}). These factors were then compared with the tolerance limits mentioned previously for *L. fortunei* (Table 2). The suspended sediment levels were obtained by filtering 5 L of water with a vacuum pump and using a Chamberland filter (retention capacity $\geq 1 \mu\text{m}$).

Samples were oven-dried (105 °C) and then weighed (precision = 0.1 mg). Suspended organic matter was obtained by ignition in a muffle (550 °C for 20 min) and weighed (precision = 0.1 mg) (APHA, 1985). For Ca²⁺ (mg.L⁻¹) determinations, samples were treated according to EPA 600/R-94/111 – Method 200.2. Measurements were made by flame atomization, using the calibration curve method with aqueous standards and a Perkin Elmer Analyst 800 spectrometer.

Data analysis

A non-metric multi-dimensional scaling method was applied to relate environmental data and the presence/absence of *L. fortunei* in the sampled stations; the stress value was calculated to measure the goodness of fit using PAST Paleontological Statistics 2.07 (Hammer *et al.*, 2001). Environmental data of a sampling station in the Paraná River (32°39'S–60°44'W; Table 3, PR),

Fig. 2. Non-metric multi-dimensional scaling of 14 sampling stations and a control station (PR).

in which *L. fortunei* has stable populations, were incorporated into the analysis.

Results

L. fortunei was found at two sampling stations only, *i.e.*, Puerto Pilcomayo (SS 12) and Puerto Las Palmas (SS 13), both on the Lower Paraguay River (Table 1). Mean larvae densities in these sampling stations were 33.18 (SD: 1.78) and 15.83 (SD: 3.87) larvae.L⁻¹, respectively. Adult density was 45 000 ind.m⁻² in SS 12. Field surveys of the rivers and associated aquatic habitats,

together with measurements of the environmental variables, reveal high hydrosedimentological and chemical variability between the sampled sites (Table 3).

The multi-dimensional scaling revealed that the sampling stations could be arranged into three groups (Fig. 2). The first includes the SS 1, 4 and 5, with extreme environmental characteristics (*e.g.*, high concentrations of suspended sediment and salinity). The second links two stations with presence of *L. fortunei* (SS 12 and 13), the Parana River station (PR) used as control, environmental characteristics optimal for the development of stable populations of the golden mussel, and SS 2 for Laguna Blanca at Río Pilcomayo National Park. The third group encompasses the other stations (Table 3).

SS 1 in the Lower Pilcomayo had a salinity of 19.65 g.L⁻¹ at the time of sampling. However, the remaining sites showed salinity values lower than 3 g.L⁻¹ (Table 3). The suspended sediment concentration in the Upper Bermejo River is more than 0.214 g.L⁻¹ (SS 1, 4, 5, 8 and 9) and only one sample site (SS 7) showed a slightly lower value (Table 3). Localities with golden mussel populations on the Lower Paraguay River had values 0.1448 g.L⁻¹ (SS 12) and 0.088 g.L⁻¹ (SS 13). Ca^{2+} concentrations at the sampling sites ranged between 2.0 and 258.0 mg.L⁻¹. The two sampling sites with populations of *L. fortunei* (SS 12 and 13) had the lowest Ca^{2+} concentration (2.0 mg.L⁻¹). Water velocity was less than 1 m.s⁻¹ for most sampling stations (Table 3); only at SS 8 did it reach a value near 1 m.s⁻¹ (0.91 m.s⁻¹) and at SS 9 it reached a higher value than 1 m.s⁻¹ (2.5 m.s⁻¹). Dissolved oxygen concentration varied from 6 to 12 mg.L⁻¹ and pH exceeded 8 at six of the locations sampled (Table 3). Transparency values were highly variable (from to see the bed in a very low depth rivers to 0.015 m; Table 3).

Discussion

The hydrological, sedimentological and chemical data, in conjunction with data on *L. fortunei* environmental tolerances taken from the literature (Table 2), were useful in assessing their ability to invade the Pilcomayo, Bermejo and Salado del Norte rivers upstream toward the Andes. The ordination analysis performed allows grouping all the sampling stations, including also sites that show the optimum environmental characteristics for the development of *L. fortunei* (SS 12, 13 and PR). This group included SS 2, which has appropriate environmental conditions for the development of the golden mussel. However, in this station, larvae, juveniles and adults were absent. This station is under the protection of National Park Service, which is largely responsible for administering environmental laws and regulations (*e.g.*, controlling the entry of exotic species), which would be acting as a barrier to stop the invasion. Also, two of the potential dispersion barriers to invasion are shown in Figure 2, where SS groups 1, 4 and 5, with high concentrations of suspended sediments and salinity, limit the spread of the golden mussel in the region (Table 2). Finally, according to Oliveira *et al.* (2011), the group with the remaining sampling stations has a combined effect of several of these and other environmental conditions, which limit the invasion of this species. Therefore, regardless of the rate of dispersal of *L. fortunei* in the Neotropical region, there appear to be three barriers that limit their dispersal and invasion. Analysis of the physicochemical parameters and hydrological characteristics of the sampled stations allowed identifying three barriers to dispersion of the golden mussel, *i.e.*, salinity, suspended sediment concentration and flow intermittency (Figs. 1 and 2). These are discussed next.

Salinity barrier

The Lower Pilcomayo has a salt concentration range of 5–60 g.L⁻¹, suggesting an input of high-salinity groundwater (Cordini, 1947). It appears as a limiting factor in Pilcomayo River (Fig. 1) 100 km upstream of its junction with the Paraguay River, where it presents a salinity of 19.65 g.L⁻¹ (SS1; Table 3). Salinity is a serious threat to freshwater ecosystems, as has been demonstrated in coastal environments, due to the changes it produces in community structure (Gonçalves *et al.*, 2007). Stable natural populations of this bivalve do not tolerate salinities above 3 g.L⁻¹ (Darrigran, 2002; Barbosa and Melo, 2009). Experimental studies revealed that *L. fortunei* could live only over three weeks with a salt concentration of 6.8 g.L⁻¹ (Deaton *et al.*, 1989).

Salinity is also a limiting barrier in the Salado del Norte River (Fig. 1). The Upper Salado del Norte River shows low salinities not above 0.5 g.L⁻¹, while downstream it reaches salinities between 10 and 100 g.L⁻¹ (Williams, 1981; Drago and Paira, 1997). In the lower end, near the confluence with the Middle Paraná River, the freshwater

of the last river flows upstream about 10 km during exceptional floods. During the prolonged “El Niño” flood of 1997–1998, salinity of this sector dropped sharply from 3–4 to < 1 g.L⁻¹. Because of the long period of flooding at that time (13 months), *L. fortunei* developed numerous metapopulations (Darrigran and Ezcurra de Drago, 2000; Ezcurra de Drago *et al.*, 2006), which phased out when the usual salinity levels were restored.

Sedimentological barrier

The limiting factor for the settlement of *L. fortunei* in the Bermejo River appeared to be the high concentration of suspended sediment (Fig. 1). The average concentration is 6 g.L⁻¹, but exceeded 40 g.L⁻¹ during floods (Drago and Amsler, 1988; Amsler and Drago, 1999). In the Upper Pilcomayo Basin, the concentration of suspended sediments is also one of the important factors that prevent the invasion of *L. fortunei*, with wash load percentages of 90% or more (Fig. 1); the average concentration is 24 g.L⁻¹ (Martín Vide *et al.*, 2007). Although salinity values in the Upper Pilcomayo River and in the first sector of the Middle Pilcomayo range between 0.1 and 0.5 g.L⁻¹, the high concentration of suspended sediments prevents the invasion of this bivalve (40–60 g.L⁻¹, Martín Vide, personal communication). Suspended sediment values in the Upper Salado del Norte River were 0.07 g.L⁻¹ during low water periods (Table 3). The data show that the concentration values in this area are high (up to 20 g.L⁻¹) during high water phases (Drago and Quirós, 1996; Drago and Paira, 1997). This concentration is a barrier to the settlement of the golden mussel in this river sector. However, along the middle sector of this river the concentrations drop sharply as sediment settles (1.0–0.07 g.L⁻¹) (Drago and Paira, 1997). Information available on transparency tolerance limits of *L. fortunei* is scarce (Table 2). Oliveira *et al.* (2011) mentioned that *L. fortunei* can live in an environment with a transparency of around 0.1–0.4 m.

Hydrological barrier

Another key factor in the middle and lower segment of the Pilcomayo River was the high intermittence of water flow (Fig. 1; Cordini, 1947), with the river dry for over 360 km, *i.e.*, from the Esmeralda Tripartite International Landmark (22°22'S–62°31'W; Fig. 1) to Cabo Primero Lugones (24°17'S–59°49'W). This sector remained dry between 1983 and 1993; downstream from Estero Patiño (24°04'S–59°50'W) it has been dry since 1973 up to the present (Martín Vide, personal communication). Intolerance of *L. fortunei* to dry conditions does not permit its surviving during the long drought phases of this river (Table 2). The Middle Salado del Norte River becomes intermittent and remains completely dry for long stretches (Drago and Paira, 1997). Furthermore,

an additional limiting factor is the high salinity in the area (Fig. 1).

Ca²⁺ water content is one of the parameters affecting the distribution of freshwater mollusks (Sprung, 1987; Ramcharan *et al.*, 1992; Vinogradov *et al.*, 1993). Information on the minimal concentration of Ca²⁺ necessary for development of *L. fortunei* is scarce (Table 2), but available data suggest it ranges from 3 (Boltovskoy *et al.*, 2006) to 3.96 mg.L⁻¹ (Darrigran, 2002). Oliveira *et al.* (2010a, 2011) discussed that in the Pantanal, on the Paraguay River, *L. fortunei* lives in places where Ca²⁺ concentrations range from 1.0 to 6.0 mg.L⁻¹. In the Lower Paraguay River (SS 12 and SS 13), the two populations studied during this fieldwork were living with Ca²⁺ concentrations of 2 mg.L⁻¹. So, Ca²⁺ concentrations were found not to be limiting the establishment of *L. fortunei* populations (Table 2).

Rate of dispersal of exotic species depends on the spatial scale and may be accelerated or inhibited by human activities (Karatayev *et al.*, 2007b). However, characterizing invasibility at a higher hierarchic scale without correctly determining the characteristics of the immediately lower hierarchy – or the invasiveness of the species – could lead to erroneous interpretations. It is unwise, for instance, to jump to a regional scale without precise data on the invasibility of local or smaller unit scales, as this renders incorrect predictions on the dispersion of the invading species. As a consequence, environments in which invasion is virtually impossible (even with man as a vector) may be taken to be potentially prone to invasion. This scenario may become real when input data used for modeling a potential distribution of *L. fortunei* include (a) inaccurate or incorrect invasiveness characteristics (e.g., a higher salinity tolerance) and (b) incorrect invasibility data. This would happen if one considered that these data are theoretical characteristics of the spatial scale under study, without knowing the characteristics of the lower scales that make up that higher spatial hierarchy (e.g., lower saline concentration, lower sediment load, or the existence of temporary water bodies). Because *L. fortunei* exhibits a jump-dispersal mechanism (Boltovskoy *et al.*, 2006), it could potentially settle upstream of its present range. However, because of the physical and chemical barriers described herein, the species is restricted to the environmentally favorable locations, but does not invade others that – because similar at a regional scale – theoretically could be susceptible to invasion.

Countries are attempting to control the rate of new biological invasions and need better ways of assessing the risks and benefits of introductions. In this sense, invasion models are tools for successfully predicting invasive species (Caley *et al.*, 2006). Interactions within an invasion process can be analyzed by means of simulations, considering an input of species and habitat features which will render an output of risk and invasion rates patterns. The advantage of modelling the potential distribution is that the possibility of an invasion can be assessed before the actual introduction of a species occurs (Peterson and

Vieglais, 2001). To reach reliable predictions, the model should be fed with accurate environmental data. According to MacIsaac *et al.* (2001), full use of pre- and post-invasion datasets (where they exist) is necessary to test concepts emerging from the models. In this paper, we present a detailed description of the factors limiting the dispersion of *L. fortunei*.

The results presented herein allow the prediction of the geographic expansion of *L. fortunei* in river systems, based on physical and chemical variables. These variables are not commonly used in regional-scale models (Oliveira *et al.*, 2010a). The findings of this study may be useful for the management of invasive species not only in the Andean tributaries of the Paraná and Paraguay rivers but also in other environments it may invade (Sousa *et al.*, 2006). Likewise, the data and results obtained can be used to prevent the invasion by the golden mussel into susceptible regions (the rest of America and Western Europe).

Acknowledgements. The present work was partially funded by Committee Research and Exploration-National Geographic Society (Grant 7824-05) as well as by FCNyM (UNLP), ANPCyT (Pict 25621) and CONICET (PIP 1017). We thank M. Lagreca (Comisión de Investigaciones Científicas-CIC, Bs.As.) for technical support and INALI (CONICET-UNL) for logistic field support.
